Abstract. Shape Expressions express formal constraints on the content of RDF graphs and are intended to be used to validate RDF documents, communicate expected graph patterns for interfaces and to generate forms and validation code. This document describes the formal semantics of the Shape Expressions language through the use of the Z Specification Language.

Keywords: RDF, RDF Graph, RDF Dataset, validation, formal schema, ShEx, RDF Validation, Z Specification Language

1 Introduction

The Shape Expressions Language (ShEx) is used to specify formal constraints on the content of RDF graphs and are intended to be used to validate RDF documents, communicate expected graph patterns for interfaces and to generate forms and validation code. ShEx can be used to:

- Describe the contents of an RDF graph
- Express invariants about an RDF triple store
- Define a predicate that can be tested against an RDF graph instance
- Define a set of rules that can be used to generate forms, validation code and other constructs in specific target languages

Information about the use, grammar and syntax of ShEx can be found at http://www.w3.org/2013/ShEx. The purpose of this document is to describe the formal semantics of the ShEx language using the Z specification language. We begin with a formal specification of the characteristics of an RDF Graph that are referenced by ShEx.

2 The RDF Data Model

Using the formal definitions in RDF 1.1 Concepts and Abstract Syntax[?], we begin with:

"An RDF graph is a set of RDF Triples"

Formally:

```
Graph == \mathbb{P} Triple
```

The specification then defines the notion of **Triple**:

"An RDF triple consists of three components:

- the $\mathit{subject},$ which is an **IRI** or a **blank node**
- the *predicate*, which is an **IRI**
- the *object*, which is an **IRI**, a **literal** or a **blank node**"

"... IRIs, literals and blank nodes are distinct and distinguishable."

The ShEx language treats **IRI**s and **blank nodes** as primitive types, so we can formally define them as Z free types:

```
[IRI, BlankNode]
```

The ShEx language can express constraints on both the type and content of **literals**, so we need to model these separately. Starting with:

"A literal in an RDF graph consists of two or three elements:

- a **lexical form**, being a Unicode string...
- a datatype IRI, being an IRI
- if and only if the datatype IRI is

http://www.w3.org/1999/02/22-rdf-syntax-ns#langString, a non-empty language tag as defined in [BCP47][?]. The language tag MUST be well-formed according to section 2.2.9 of [BCP47][?]."

We model this by defining String and Language Tag as free types:

```
[String, Language Tag]
```

And then use them in the definition the two flavors of *RDFLiteral*, plain literal and typed literal::

```
TypedLiteral \triangleq [lexicalForm : String; \ dataType : IRI \mid dataType \neq XSD\_String] \\ PlainLiteral \triangleq [lexicalForm : String; \ dataType : IRI; \ langTag : LanguageTag \mid \\ dataType = XSD\_String] \\ RDFLiteral ::= pl\langle\langle PlainLiteral\rangle\rangle \mid tl\langle\langle TypedLiteral\rangle\rangle
```

The RDF 1.1 specification the defines RDFTerm as:

"IRIs, literals and blank nodes are collectively known as RDF terms

```
RDFTerm ::= iri\langle\langle IRI \rangle\rangle \mid literal\langle\langle RDFLiteral \rangle\rangle \mid bnode\langle\langle BlankNode \rangle\rangle
```

We are now in the position to complete the definition of Triple as a tuple consisting of three constrained RDFTerms:

The ShEx language uses the following functions:

subjects – return set of triples in a graph triples whose subject is a given RDFTerm

objects – return set of objects in Graph

It is also useful to define a couple of well known URI's for future reference:

```
XSD\_String, RDF\_Resource : IRI
```

This completes the formal definition of *Graph*, *Triple*, *RDFTerm* and their components, which we can now use to describe the relationship between an *ShEx Schema* and an RDF graph.

3 Shape Expression Evaluation

A Shape Expression *Schema* is a collection of labeled rules where exactly one rule in the collection is identified as the outermost or "starting" rule. In addition, any rule that is referenced within the *Schema* is also itself a member of the *Schema* Formally:

```
Schema \\ rules: Label \rightarrow Rule \\ start: Label \\ \hline start \in \operatorname{dom} rules \\ \forall r: \operatorname{ran} rules \bullet \\ (r \in \operatorname{ran} \operatorname{group} \Rightarrow (\operatorname{group} \cdot r).rule \in \operatorname{dom} rules) \land \\ (r \in \operatorname{ran} \operatorname{and} \Rightarrow \operatorname{ran}(\operatorname{and} \cdot r) \subseteq \operatorname{dom} rules) \land \\ (r \in \operatorname{ran} \operatorname{xor} \Rightarrow \operatorname{ran}(\operatorname{xor} \cdot r) \subseteq \operatorname{dom} rules) \land \\ (r \in \operatorname{ran} \operatorname{arc} \land (\operatorname{arc} \cdot r).valueSpec \in \operatorname{ran} valueRef \Rightarrow \\ (\operatorname{valueRef} \cdot (\operatorname{arc} \cdot r).valueSpec) \in \operatorname{dom} rules) \\ \hline
```

While existing ShEx implementations define a rule Label as being either an IRI or a BlankNode, the type of Label does not impact the evaluation semantics. For our purposes, we can simply define it as a separate free type:

```
[Label]
```

The validity of a given RDF *Graph* is determined by taking the *start Rule* of a *ShEx Schema* and a subject *IRI* and evaluating the validity of the *Rule* against the subset of the triples in the graph having the supplied *subject*. It is necessary that this evaluation be done in the *context* of the entire *Schema* and *Graph*, as the *start* rule in the schema will usually reference other *rules* and it will frequently be the case that the *objects* of the subject graphs will (recursively) reference other graph subjects.

Formally, the evaluate function takes a Schema, a Graph and a subject IRI and, if the start Rule in the Schema, when evaluated against the subject graph in the context of the starting Schema and graph, returns either nomatch (\mathbb{Z}) or pass (\mathbb{P}) then the function returns pass. In all other cases, the function returns fail (f).

```
\begin{array}{l} evaluate: Schema \rightarrow Graph \rightarrow IRI \rightarrow OptValidity \\ \forall s: Schema; \ g: Graph; \ i: IRI; \ v: OptValidity; \ ec: EvalContext \mid \\ ec. graph = g \land ec. schema = s \bullet \\ evaluate \ s \ g \ i = \\ & \ \textbf{if} \ evalRule \ ec \ (subjects \ (iri \ i) \ g) \ (s.rules \ s.start) \in \{\mathbb{z}, \mathbb{p}\} \\ & \ \textbf{then} \ \mathbb{p} \ \textbf{else} \ \mathbb{f} \end{array}
```

4 Rule Evaluation

A ShEx Rule is a set of constraints that can be evaluated against an RDF Graph in the context of a given Schema and RDF Graph:

```
EvalContext = [schema : Schema; graph : Graph]
```

The *Graph* being evaluated does not necessarily have to be a subset of the *Graph* in *EvalContext*, and may also have more than one *subject*. While the *evaluate* function described earlier in this section actually ensures that both of these conditions are true, it is envisioned that the *eval* function may have other applications beyond the scope of the *evaluate* function itself.

Formally, the *evalRule* function takes an *EvalContext*, a *Graph* and a *Rule* and returns one of the following:

- Pass (p) the supplied *Graph* satisfied the evaluation *Rule*
- Fail (f) the supplied *Graph* did not satisfy the evaluation *Rule*
- Nomatch (z) an optional GroupRule was encountered and there were no matching triples
- **Dunno** (\varnothing) an *ArcRule* was encountered with a minimum cardinality of 0 and there were no matching triples
- **Error**(ε) an *XorRule* was evaluated and two or more components passed the evaluation.

```
OptValidity ::= p \mid f \mid z \mid \varnothing \mid \varepsilon
```

A *Rule* can take one of four forms. Each will be formally described later in this document, but informally they are:

- ArcRule selects a subset of the graph having predicates that match criteria described in the rule and and validates the objects of this subset
- GroupRule identifies a Rule and declares it as optional and/or describes a set of external Actions to be evaluated if the inner Rule passes.
- AndRule identifies a set of Rules, all of which must pass when evaluated against the supplied Graph and EvalContext
- XorRule identifies a set of Rules, exactly one of which must pass when evaluated against the supplied Graph and EvalContext

```
Rule ::= arc\langle\langle ArcRule\rangle\rangle \mid group\langle\langle GroupRule\rangle\rangle \mid and\langle\langle AndRule\rangle\rangle \mid xor\langle\langle XorRule\rangle\rangle
```

```
evalRule: EvalContext \rightarrow Graph \rightarrow Rule \rightarrow OptValidity
\forall ec: EvalContext; \ g: Graph; \ r: Rule \bullet evalRule \ ec \ g \ r =
\textbf{if} \ r \in \text{ran} \ arc
\textbf{then} \ evalArcRule \ ec \ g \ (arc \cdot r)
\textbf{else} \ \textbf{if} \ r \in \text{ran} \ group
\textbf{then} \ evalGroupRule \ ec \ g \ (group \cdot r)
\textbf{else} \ \textbf{if} \ r \in \text{ran} \ and
\textbf{then} \ evalAndRule \ ec \ g \ (and \cdot r)
\textbf{else}
evalXorRule \ ec \ g \ (xor \cdot r)
```

The function below is used to execute the rules that referenced by GroupRules, AndRules and OrRules. Its purpose is to de-reference the supplied Label and invoke evalRule with the result. This is not explicitly represented because the Z specification language does not allow cyclic dependencies. Note that this function is undefined if Label is not in EvalContext

```
evalRuleLabel: EvalContext \rightarrow Graph \rightarrow Label \rightarrow OptValidity \forall \, ec: EvalContext; \, \, l: Label \, \bullet \, l \in \text{dom } ec.schema.rules
```

4.1 ArcRule evaluation

The ArcRule is used to select the subset of the graph having a given predicate or predicates and to determine whether the cardinality and/or "type" of this subset matches a supplied criteria. The rule itself consists of a PredicateFilter to select the triples, an ObjectSpecification to evaluate the result, a optional min and max cardinality and a (possibly empty) set of Actions:

```
ArcRule \\ filter: PredicateFilter \\ valueSpec: ObjectSpecification \\ min, max: \mathbb{N}[0...1] \\ actions: \mathbb{P} \ Action \\ \hline (\#min = 1 \land \#max = 1) \Rightarrow v \ min \leq v \ max
```

ArcRule evaluation consists of:

- 1. Selecting all of the triples in *Graph* having predicates that match *Predicate-Filter*
- 2. If the number of triples from the previous step is 0, return either nomatch (\mathbb{Z}) if min is 0 otherwise $dunno(\emptyset)$.
- 3. If min is specified and the number of triples from the previous step is ; min then return fail (f)
- 4. If max is specified and the number of triples from the previous step is i, max then return fail (f)
- 5. Evaluate the object of each of the triples in the set against *ObjectSpecification*. If any of the evaluations fail, return fail (f).
- 6. Return the result of evaluating actions against the matching triples.

```
\begin{array}{c} evalArcRule: EvalContext \rightarrow Graph \rightarrow ArcRule \rightarrow OptValidity \\ \forall ec: EvalContext; \ g, sg: Graph; \ ar: ArcRule \mid \\ sg = evalPredicateFilter \ ar. filter \ ec. graph \bullet \\ evalArcRule \ ec \ g \ ar = \\ \textbf{if} \ \#ar.min = 1 \land \#sg = 0 \land v \ ar.min = 0 \\ \textbf{then} \ \mathbb{Z} \\ \textbf{else if} \ \#sg = 0 \\ \textbf{then} \ \varnothing \\ \textbf{else if} \ (\#ar.min = 1 \land \#sg < v \ ar.min) \lor \\ (\#ar.max = 1 \land \#sg > v \ ar.max) \\ \textbf{then} \ \mathbb{f} \\ \textbf{else if} \ evalObjectSpecification \ ec \ ar.valueSpec \ sg = \mathbb{p} \\ \textbf{then} \ dispatch \ ar.actions \ sg \ ec \\ \textbf{evalObjectSpecification \ ec \ ar.valueSpec \ sg} \end{array}
```

PredicateFilter Validation A PredicateFilter can be one of:

- an pfIRI the IRI of a specific predicate or the IRIstem that defines a set of predicates
- pfWild an expression that matches any predicate except those matching the (possibly empty) set of IRIorStems

```
IRIorStem ::= iosi\langle\langle IRI \rangle\rangle \mid ioss\langle\langle IRIstem \rangle\rangle

PredicateFilter ::= pfIRI\langle\langle IRIorStem \rangle\rangle \mid pfWild\langle\langle \mathbb{P}|IRIorStem \rangle\rangle
```

An *IRIstem* matches any *IRI* whose stringified representation begins with the stringified representation of *IRIstem* according to standard IRI matching rules [?]. This is represented by the function:

[IRIstem]

```
IRIstemRange:IRIstem \rightarrow \mathbb{P}IRI
```

evalPredicateFilter returns all of the triples in a Graph whose predicate matches the supplied PredicateFilter:

evalIRIorStem returns all of the triples in a Graph matching the supplied IRI-orStem

```
evalIRIorStem: IRIorStem \rightarrow Graph \rightarrow Graph
\forall e: IRIorStem; \ g: Graph \bullet evalIRIorStem \ e \ g =
\text{if} \ e \in \text{ran } iosi \ \text{then} \ \{t: g \mid iri \cdot t.p = iosi \cdot e\}
\text{else} \ \{t: g \mid iri \cdot t.p \in IRIstemRange \ (ioss \cdot e)\}
```

evalWild returns all of the triples in a Graph that do not match an entry in the set of IRIorStems.

```
\begin{array}{c} \hline evalWild: \mathbb{P} \ IRIorStem \ \ \rightarrow \ Graph \ \ \rightarrow \ Graph \\ \forall \ es: \mathbb{P} \ IRIorStem; \ g: Graph \bullet \ evalWild \ es \ g = \\ \{t: g \mid t \notin \bigcup \{e: es \bullet \ evalIRIorStem \ e \ g\}\} \end{array}
```

ObjectSpecification evaluation *ObjectSpecification* specifies a set of possible values for an *RDFTerm* and takes one of the following forms:

- Value Type matches Literals having a specified data type
- ValueSet matches IRIs or Literals that match one or more of the expressions in the specified set
- Value Wild matches any target except those matching the (possibly empty) set of IRIstems
- ValueReference matches any target that is considered valid according the Rule identified by Label.

```
\begin{split} Match Value &::= mviri \langle \langle IRI \rangle \rangle \mid mviris \langle \langle IRIstem \rangle \rangle \mid \\ & mvlit \langle \langle RDFLiteral \rangle \rangle \\ Object Specification &::= value Type \langle \langle IRI \rangle \rangle \mid \\ & value Set \langle \langle \mathbb{P} \ Match \ Value \rangle \rangle \mid \\ & os \ Wild \langle \langle \mathbb{P} \ Match \ Value \rangle \rangle \mid \\ & value Ref \langle \langle Label \rangle \rangle \end{split}
```

evalObjectSpecification – returns pass (\mathbb{p}) if all of the triples in a Graph match the supplied ObjectSpecification, otherwise fail (\mathbb{f})

```
\begin{array}{c} evalObjectSpecification: EvalContext \rightarrow ObjectSpecification \rightarrow Graph \rightarrow \\ OptValidity \\ \\ \forall \ ec: EvalContext; \ os: ObjectSpecification; \ g: Graph \bullet \\ evalObjectSpecification \ ec \ os \ g = \\ \text{if} \ \forall \ t: \ g \bullet evalObjectSpecificationTriple \ ec \ os \ t.o = \mathbb{p} \ \textbf{then} \ \mathbb{p} \\ \text{else} \ \mathbb{f} \end{array}
```

evalValueType – returns pass if the supplied RDFTerm is:

- type *literal* and whose *dataType* matches ValueType
- type IRI and ValueType is type RDF_Literal

```
evalValueType: IRI \rightarrow RDFTerm \rightarrow OptValidity
\forall vt: IRI; \ t: RDFTerm; \ l: RDFLiteral \bullet evalValueType \ vt \ t =
\mathbf{if} \ vt = RDF\_Resource \land t \in \operatorname{ran} iri \ \mathbf{then} \ \mathbb{p}
\mathbf{else} \ \mathbf{if} \ t \in \operatorname{ran} literal \land l = (literal \cdot t) \land
((l \in \operatorname{ran} pl \land (pl \cdot l). dataType = vt) \lor
(l \in \operatorname{ran} tl \land (tl \cdot l). dataType = vt)) \ \mathbf{then} \ \mathbb{p}
\mathbf{else} \ \mathbb{f}
```

evalValueSet – return p if the supplied RDFTerm is a member of MatchValue

```
evalValueSet: \mathbb{P} \ MatchValue \rightarrow RDFTerm \rightarrow OptValidity
\forall \ mvs: \mathbb{P} \ MatchValue; \ t: RDFTerm \bullet \ evalValueSet \ mvs \ t =
\text{if} \ \exists \ mv: mvs \ \bullet
((mv \in \text{ran} \ mviri \land (iri \cdot t) = mviri \cdot mv) \lor
(mv \in \text{ran} \ mviris \land (iri \cdot t) \in IRIstemRange \ (mviris \cdot mv)) \lor
(mvlit \cdot mv = literal \cdot t))
\text{then} \ \mathbb{p}
\text{else} \ \mathbb{f}
```

evalValueWild – return pass (p) if the supplied RDFTerm is not a member of MatchValue.

```
evalValueWild: \mathbb{P}\ MatchValue \rightarrow RDFTerm \rightarrow OptValidity
\forall\ mvs: \mathbb{P}\ MatchValue;\ t: RDFTerm \bullet evalValueWild\ mvs\ t =
\mathbf{if}\ evalValueSet\ mvs\ t = \mathbb{p}\ \mathbf{then}\ \mathbb{f}\ \mathbf{else}\ \mathbb{p}
```

evalValueReference – return p if the subgraph of the EvalContext graph whose subjects match the supplied RDFTerm satisfies the ValueReference rule.

```
\begin{array}{c} evalValueReference: EvalContext \rightarrow Label \rightarrow RDFTerm \rightarrow OptValidity \\ \forall ec: EvalContext; \ vr: Label; \ t: RDFTerm \bullet \\ evalValueReference \ ec \ vr \ t = \\ & \ \textbf{if} \ t \notin \text{ran literal then } \ evalRuleLabel \ ec \ (subjects \ t \ ec. graph) \ vr \\ & \ \textbf{else} \ \textbf{f} \end{array}
```

4.2 GroupRule evaluation

A *GroupRule* serves two purposes. The first is to declare that a referenced rule is to be treated as "optional", which, in this case means that if (a) the referenced rule returned dunno (\varnothing), (meaning an ArcRule was encountered that had no matching predicates and a non-zero minimum cardinality) the group rule returns nomatch (\mathbb{Z}). An optional GroupRule also treats an error situation as a fail (\mathbb{f}).

The second purpose of a group rule is to allow a set of external *actions* to be evaluated whenever the referenced rule returns pass (p).

```
OPT ::= OPTIONAL \mid REQUIRED

GroupRule \triangleq [rule : Label; opt : OPT; actions : \mathbb{P} Action]
```

evalGroupRule evaluates Rule, applies opt and, if the result is pass (p) evaluates the actions with respect the passing Graph

```
\begin{array}{c} evalGroupRule: EvalContext \rightarrow Graph \rightarrow GroupRule \rightarrow OptValidity \\ \forall ec: EvalContext; \ g: Graph; \ gr: GroupRule \bullet evalGroupRule \ ec \ g \ gr = \\ \textbf{if} \ evalRuleLabel \ ec \ g \ gr.rule = \varnothing \land gr.opt = OPTIONAL \\ \textbf{then} \ \Z \\ \textbf{else \ if} \ evalRuleLabel \ ec \ g \ gr.rule = \varnothing \land gr.opt = OPTIONAL \\ \textbf{then} \ \P \\ \textbf{else \ if} \ evalRuleLabel \ ec \ g \ gr.rule = \varnothing \\ \textbf{then} \ dispatch \ gr.actions \ g \ ec \\ \textbf{else} \ evalRuleLabel \ ec \ g \ gr.rule \end{array}
```

4.3 AndRule evaluation

An AndRule consists of a set of one or more Rules, whose evaluation is determined by the following table:

And	Ø	\mathbb{Z}	f	\mathbb{P}	ε			
Ø	Ø	Ø	f	f	ε			
\mathbb{Z}	Ø	\mathbb{Z}	f	\mathbb{P}	ε			
f	f	f	f	f	ε			
\mathbb{P}	f	\mathbb{P}	f	\mathbb{P}	ε			
ε	ε	ε	ε	ε	ε			

The formal implementation of which will be realized in the corresponding function:

```
And: OptValidity \rightarrow OptValidity \rightarrow OptValidity
```

Observing that the above table is a monoid with nomatch (z) as an identity element, evalAndRule can be applied using the standard functional pattern:

 $AndRule == seq_1 Label$

```
eval And Rule: Eval Context 
ightarrow Graph 
ightarrow And Rule 
ightarrow Opt Validity orall ec: Eval Context; \ g: Graph; \ r: And Rule 
ightarrow eval And Rule \ ec \ g \ r = fold r \ And \ \mathbb{Z} \ (map \ (eval Rule Label \ ec \ g) \ r)
```

4.4 XorRule evaluation

An XorRule consists of a set of one or more Rules, whose evaluation is determined by the following table:

Xor	Ø	\mathbb{Z}	f	\mathbb{P}	ε
Ø	Ø	\mathbb{Z}	Ø	p	ε
\mathbb{Z}	\mathbb{Z}	\mathbb{Z}	\mathbb{Z}	\mathbb{P}	ε
f	Ø	\mathbb{Z}	f	\mathbb{P}	ε
\mathbb{P}	p	\mathbb{P}	\mathbb{P}	ε	ε
ε	ε	ε	ε	ε	ε

The formal implementation of which will be realized in the corresponding function:

 $Xor: OptValidity \rightarrow OptValidity \rightarrow OptValidity$

As with the And function above, Xor is a monoid whose identity is fail (f) resulting in the following definition for evalXorRule

```
XorRule == seq_1 Label
```

```
\begin{array}{|c|c|c|c|c|}\hline eval Xor Rule : Eval Context \rightarrow Graph \rightarrow Xor Rule \rightarrow Opt Validity\\ \hline \forall ec : Eval Context; \ g : Graph; \ r : Xor Rule \bullet\\ eval Xor Rule \ ec \ g \ r =\\ fold r \ Xor \ f \ (map\ (eval Rule Label\ ec\ g)\ r) \end{array}
```

5 Action evaluation

The dispatch function allows the evaluation / execution of arbitrary external "Actions". While the evaluation of an Action can (obviously) have side effects outside the context of the ShEx environment, it must be side effect free within the execution context. In particular, an Action may not change anything in the EvalContext or passing Graph The action dispatcher exists to allow external events to happen. Parameters:

- EvalContext the evaluation context
- Actions the set of Actions associated with the associated GroupRule or ArcRule
- Graph the Graph that passed the associated Rule.

The dispatch function usually returns pass (p) or fail (f), although there may also be cases for other OptValidity values in certain circumstances. The dispatch function always returns pass (p) if the set of actions is empty.

[Action]

```
\begin{aligned} dispatch : \mathbb{P} \ Action \rightarrow Graph \rightarrow EvalContext \rightarrow OptValidity \\ \forall \ as : \mathbb{P} \ Action; \ g : Graph; \ ec : EvalContext \bullet \\ as = \emptyset \Rightarrow dispatch \ as \ g \ ec = \mathbb{p} \end{aligned}
```

6 Appendix

6.1 Foldr

The foldr function is the standard functional pattern, which takes a binary function of type T, an identity function for type T, a sequence of type T and returns the result of applying the function to the right to left pairs of the sequence.

```
[T] = foldr: (T \to T \to T) \to T \to \operatorname{seq} T \to T
\forall f: T \to T \to T; id: T; xs: \operatorname{seq} T \bullet foldr f id xs = 
\text{if } xs = \langle \rangle \text{ then } id
\text{else } f \text{ (head } xs \text{) (foldr } f \text{ id (tail } xs \text{))}
```

6.2 Map

The map function takes a function from type A to type B and applies it to all members in the supplied sequence

```
[A, B] = \frac{[A, B]}{map : (A \to B) \to \text{seq } A \to \text{seq } B}
\forall f : A \to B; \ xs : \text{seq } A \bullet map \ f \ xs = \text{if } xs = \langle \rangle \ \textbf{then } \langle \rangle
\text{else } \langle f \ (head \ xs) \rangle \cap map \ f \ (tail \ xs)
```

6.3 Helper Functions

Z uses the notion of free type definitions in the form:

```
Free Type ::= constructor \langle \langle source \rangle \rangle
```

which introduces a collection of constants of type Free Type, one for each element of the set source. constructor is an injective function from source to Free Type:

```
constructor ::= source \rightarrow Free Type
```

In the models that follow, there is a need to reverse this – to find the *source* for a given FreeType instance. The · function exists for this purpose. As an example, if one were to define:

```
TravelDirections ::= bus \langle \langle BusDirections \rangle \rangle \mid walking \langle \langle WalkingDirections \rangle \rangle
```

If one is supplied with an instance of Travel , one can convert it to the appropriate type by:

```
x: TravelDirections \\ \vdash \\ \textbf{if } x \in \operatorname{ran} bus \textbf{ then } bus \cdot x \textbf{ else } walking \cdot x
```

```
[X, Y] = [X, Y]
-\cdot -: (X \rightarrowtail Y) \times Y \to X
\forall y : Y; f : X \rightarrowtail Y \bullet f \cdot y = (\mu x : \text{dom } f \mid f x = y)
```

As Z has no notion of absence, it is convenient to add a bit of syntactic sugar.

$$T[0\mathinner{.\,.} 1] == \{s: \mathbb{P}\ T\mid \#s \leq 1\}$$

It is also useful to provide a shorthand for addressing the content of singletons:
